We study the impact of asymmetric information in a general credit model, where the default is triggered when a fundamental diffusion process of the firm passes below a random threshold. Inspired by some recent technical default events during the financial crisis, we consider the role of the firm's managers who choose the level of the default threshold and have complete information. However, other investors on the market only have partial observations either on the process or on the threshold. We specify the accessible information for different types of investors. Besides the framework of progressive enlargement of filtrations usually adopted in the credit risk modelling, we also combine the results on initial enlargement of filtrations to deal with the uncertainty on the default threshold. We consider several types of investors who have different information levels and we compute the default probabilities in each case. Numerical illustrations show that the insiders who have extra information on the default threshold obtain better estimations of the default probability than the standard market investors.

Keywords: credit risk; insider; enlargement of filtration

1. Introduction

In the credit risk analysis, it is crucial to model the default event and to forecast the default probabilities for pricing and risk management purposes. In the literature there exist two main modelling approaches: the structural one and the reduced-form one. The structural approach provides a convincing economic interpretation, where the original idea goes back to the paper of Merton [20]. The default is triggered when a fundamental process X of the firm passes below a deterministic threshold L . The fundamental process may represent the asset value or the total cash flow. The level L is chosen by the firm's managers according to some economic criterions, for example, maximizing the equity value. The default time defined in the structural approach is a predictable stopping time and is considered as an observable event once the process approaches the threshold. In the reduced-form approach, the default is assumed to arrive in a more 'surprising' way, especially in the short term. The uncertainty is often characterized by the level of the credit spread or the default intensity. The model parameters can be calibrated from market data.

The links between the two approaches have been well studied by many authors. There are in general two methods to introduce short-term default risks in a classical structural model. The first way is to consider a generalized first-passage model, where the default threshold L is supposed to be random (e.g. [7,10,18]). The second way is to suppose that

*Email: caroline.hillairet@polytechnique.edu

†Email: jiao@math.jussieu.fr

the process X is partially observed by the investors (e.g. [2–4,6,12,16]). In both cases, the information accessibility plays an important role.

Let us consider the first-passage model in a general setting. Let $(\Omega, \mathcal{A}, \mathbb{P})$ be a probability space where \mathcal{A} is a σ -algebra of Ω representing the total information on the market. We consider a firm and model its default time as the first time that a continuous time process $(X_t)_{t \geq 0}$ reaches some default barrier L , i.e.

$$\tau = \inf\{t : X_t \leq L\}, \quad \text{where } X_0 > L \quad (1.1)$$

with the convention that $\inf \emptyset = +\infty$. Denote by $\mathbb{F} = (\mathcal{F}_t)_{t \geq 0}$ the filtration generated by the process X , i.e. $\mathcal{F}_t = \sigma(X_s, s \leq t) \vee \mathcal{N}$ satisfying the usual conditions, where \mathcal{N} denotes the \mathbb{P} null sets. We introduce the decreasing process X^* defined as $X_t^* = \inf\{X_s, s \leq t\}$. Then, (1.1) can be rewritten as

$$\tau = \inf\{t : X_t^* = L\}. \quad (1.2)$$

Note that the information of X_t^* is contained in the σ -algebra \mathcal{F}_t .

Such construction of a default time adapts to both structural and reduced-form approaches of the default modelling. In the structural approach models, L is a constant or a deterministic function $L(t)$, then τ defined in (1.1) is a predictable \mathbb{F} -stopping time (since the firm value $(X_t)_{t \geq 0}$ is a continuous time process). In the reduced-form approach¹, the default barrier L is unknown and is described as a random variable in \mathcal{A} . In the widely used Cox Model [18], the barrier L is supposed to be independent of \mathcal{F}_∞ and the law of L is known. In the incomplete information models such as [6,12,16], the whole process X cannot be fully observed, so the information concerning X is represented by some sub-filtration of \mathbb{F} . In all the models, the default probabilities are computed with respect to the observable information.

In this work, we are especially interested in the information asymmetry on the default threshold L . This is motivated by some recent ‘technical default events’ during the crisis: the firm is still in a relatively healthy situation, nevertheless, the managers have decided to close the activities and the default occurs (see Leland [19]). Hence, the default barrier in this case is a random variable whose value is chosen by the managers. In the literature, the information on the value process of the firm has been thoroughly studied. However, only few works concentrate on the default threshold. The information asymmetry on both the underlying process X and the default barrier L has been considered in Giesecke [9] and Giesecke and Goldberg [10], where the information flow for the managers, who know the default barrier, remains \mathbb{F} . Our approach is different: we consider the default threshold to be an exogenous source of risk and we add the knowledge on L to the whole information flow. The information of the managers then becomes $\mathbb{F} \vee \sigma(L)$. We study the problem by using the theory of enlargement of filtrations. In addition, we consider another type of investors, the insiders, who do not have the full access to the threshold value, but know some extra information on it compared with other market investors. We compute conditional default probabilities for these different investors and we show the importance of the information level for their estimations of default probabilities.

The rest of this paper is organized as follows. In Section 2, we introduce different information structures for various agents on the market. We distinguish the role of the managers who choose the default barrier L , the insiders who have information on L and the investors who only observe the occurrence of the default. We precise the mathematical hypotheses, using the language of enlargement of filtrations. Section 3 is devoted to the

explicit calculations on the conditional default probabilities. We then give numerical illustrations in Section 4 to quantify how different partial information impacts the estimations of the default probabilities.

2. The informational structure

On the financial market, the available information for each agent is various. On one hand, there is a strong information asymmetry between the managers and the investors of the firm. The important point is that the managers have prior information on whether the firm will default and the timing of the default. On the other hand, market investors do have different information. We now describe the different information concerning the firm and the threshold: we will consider four levels of information on the default threshold L and the underlying process X . In the following, we suppose that the default barrier is fixed at the initial date by the manager as the realization of the random variable L , and that all investors observe the occurrence of the default.

2.1 Full information

The managers have perfect information on the firm. At any time t , they know the continuous firm value, together with the default barrier. In other words, the managers have complete information on both X and L . The information of the managers – called the full information – is then given at time $t \geq 0$ by

$$\mathcal{G}_t^M := \mathcal{F}_t \vee \sigma(L).$$

The filtration $\mathbb{G}^M = (\mathcal{G}_t^M)_{t \geq 0}$ is in fact the initial enlargement of the filtration \mathbb{F} with the random variable L . For the manager, τ is a predictable \mathbb{G}^M -stopping time. Let us make precise the nature of this initial information.

Assumption 2.1. We assume that L is an \mathcal{A} -measurable random variable with values in \mathbb{R} , which satisfies the assumption:

$$\mathbb{P}(L \in \cdot | \mathcal{F}_t)(\omega) \sim \mathbb{P}(L \in \cdot) \text{ for all } t \text{ for } \mathbb{P} \text{ almost all } \omega \in \Omega.$$

Remark. Assumption 2.1 is satisfied, if L is independent of \mathcal{F}_∞ .

Assumption 2.1 is the standard assumption by Jacod [14,15]. We denote by $P_t^L(\omega, dx)$ a regular version of the conditional law of L given \mathcal{F}_t and by P^L the law of L . According to Jacod, there exists a measurable version of the conditional density $p_t(x)(\omega) = (dP_t^L/dP^L)(\omega, x)$, which is a (\mathbb{F}, \mathbb{P}) -martingale and for all $t \geq 0$, $p_t(L) > 0$ \mathbb{P} almost surely.

Gorud et al. [11] proved that Assumption 2.1 is equivalent to the existence of a probability measure equivalent to \mathbb{P} and under which for any $t \geq 0$, \mathcal{F}_t and $\sigma(L)$ are independent. We consider the only one, denoted by \mathbb{Q}^L , which is identical to \mathbb{P} on \mathcal{F}_∞ . The probability measure \mathbb{Q}^L is characterized by the density process

$$E_{\mathbb{Q}^L} \left[\frac{d\mathbb{P}}{d\mathbb{Q}^L} | \mathcal{G}_t^M \right] = p_t(L). \quad (2.1)$$

It will play a key role in the computation of the conditional default probability.

2.2 Progressive information

The progressive information is the information level of an ordinary investor who observes the process X , but does not have any knowledge on the barrier L , except that he observes at time t whether the default has occurred up to t and if so, the exact timing of default. His information is given as the progressive enlargement of filtration of \mathbb{F} with τ .

$$\mathbb{G} = (\mathcal{G}_t)_{t \geq 0} \quad \text{with} \quad \mathcal{G}_t = \mathcal{F}_t \vee \mathcal{D}_t,$$

where $\mathbb{D} = (\mathcal{D}_t = \cup_{s > t} \sigma(\tau \wedge s))_{t \geq 0}$ is the minimal right-continuous filtration which makes τ a \mathbb{D} -stopping time. The filtration $\mathbb{G} = (\mathcal{G}_t)_{t \geq 0}$ corresponds to the standard information flow in the credit modelling. We call this information the ‘progressive information’ on L . We see that the filtration \mathbb{G}^M is larger than \mathbb{G} .

Remark. If L is independent of \mathcal{F}_∞ , then the so-called (H)-hypothesis is satisfied: every (\mathbb{F}, \mathbb{P}) local martingale is also a (\mathbb{G}, \mathbb{P}) local martingale. The (H)-hypothesis is equivalent to the equality $\mathbb{P}(\tau > t | \mathcal{F}_t) = \mathbb{P}(\tau > t | \mathcal{F}_\infty)$ for all $t \geq 0$. This hypothesis is standard in the credit risk modelling. For example, the widely used Cox process model [18] satisfies this hypothesis.

2.3 Noisy full information

We now consider an intermediary case: the case of an insider who is an investor having additional observations on L besides the information on \mathbb{D} and on \mathbb{F} . We assume that the additional information on the barrier L changes through time: the knowledge on L is distorted by an independent noise, and is getting to him clearer as time evolves. More precisely, we suppose that this insider observes $L_s = L + \epsilon_s$ at time s with $(\epsilon_s)_{s \geq 0}$ being an independent noise perturbing the information on L . The information of the insider is then given by the following filtration $\mathbb{G}^I = (\mathcal{G}_t^I)_{t \geq 0}$ and is denoted as the ‘noisy full information’:

Assumption 2.2. For any $t \geq 0$, $\mathcal{G}_t^I = \mathcal{F}_t^I \vee \mathcal{D}_t$ where $\mathcal{F}_t^I = \cap_{u > t} (\mathcal{F}_u \vee \sigma(L_s, s \leq u))$, $L_s = L + \epsilon_s$ with

- $\epsilon = \{\epsilon_t, t \geq 0\}$ is independent of $\mathcal{F}_\infty \vee \sigma(L)$.
- $\mathbb{P}(L \in \cdot | \mathcal{F}_t)(\omega) \sim \mathbb{P}(L \in \cdot)$ for all t for \mathbb{P} almost all $\omega \in \Omega$.

If we work on a finite horizon T , the last two assumptions are

- $\epsilon = \{\epsilon_t, t \leq T\}$ is independent of $\mathcal{F}_T \vee \sigma(L)$,
- $\mathbb{P}(L \in \cdot | \mathcal{F}_t)(\omega) \sim \mathbb{P}(L \in \cdot)$ for all $t \in [0, T[$ for \mathbb{P} almost all $\omega \in \Omega$.

The process ϵ represents an additional noise that perturbs the knowledge of the barrier L . Therefore, one expects in general that the variance of the noise decreases to zero as time t goes to infinity.

2.4 Delayed information

In this subsection, we consider the case where the process X driving the default risk is not totally observable for all agents. We suppose that at date 0, all investors are completely informed on the firm value. Later on, they will be differently informed on the process X . Let us assume in the sequel that the process X is associated with a standard Brownian

motion B (for example, X is a geometric Brownian motion or the solution of some SDE). Let \mathcal{N} denote the \mathbb{P} null sets and we assume that $\mathcal{F}_t = \sigma(B_s, s \leq t) \vee \mathcal{N}$, where $\mathbb{F} = (\mathcal{F}_t)_{t \geq 0}$ represents the information of an investor having complete information of the fundamental process X . Most investors on the market only have an incomplete observation described by an auxiliary filtration of \mathbb{F} . In the literature, there are several ways to describe the incomplete information.

Example 2.3 (Noisy information). A structural type model with deterministic barrier is studied in [3]. The partial information is represented by an auxiliary process β depending on some noisy signal of the process X . The information of an investor observing the noisy signal of X is represented by the filtration $\mathcal{F}_t^\beta := \sigma(\beta_s, s \leq t) \vee \mathcal{N}$.

Example 2.4 (Delayed information). The investors may have a delayed (continuous or discrete) observation of the fundamental process X ; this type of models has been considered, among others, by [4,6,12,16]. In this case, the observable information is characterized by a sub-filtration $\mathbb{F}^D = (\mathcal{F}_t^D)_{t \geq 0}$ of \mathbb{F} , constructed by either a time change (continuously delayed filtration) or by a discretely delayed filtration.

In the following, we are particularly interested in the delayed information case. Let

$$\mathcal{F}_t^D = \begin{cases} \mathcal{F}_0, & \text{if } t \leq \delta(t), \\ \mathcal{F}_{t-\delta(t)}, & \text{if } t > \delta(t), \end{cases}$$

where $\delta(t)$ is some function on t . The above formulation covers the constant delay time model where $\delta(t) = \delta$ (see [4,12]) and the discrete observation model where $\delta(t) = t - t_i^{(m)}$, $t_i^{(m)} \leq t < t_{i+1}^{(m)}$ where $0 = t_0^{(m)} < t_1^{(m)} < \dots < t_m^{(m)} = T$ are the only discrete dates on which the $(\mathcal{F}_t)_{t \geq 0}$ information may be renewed (release dates of the accounting reports of the firm, for example, see [6,16]). In this case, the information of the investors is represented by the progressive enlargement of filtration of \mathbb{F}^D with τ :

$$\mathcal{G}_t^D := \mathcal{F}_t^D \vee \mathcal{D}_t.$$

We call the information related to the filtration $\mathbb{G}^D = (\mathcal{G}_t^D)_{t \geq 0}$ as the ‘delayed information’.

3. Default probabilities with information asymmetry

Our aim is to compute the conditional probabilities of default with respect to the different filtrations introduced in the previous section. More precisely, we compute $\mathbb{P}(\tau > \theta | \mathcal{H}_t)$ for all $t < \theta$, where the filtration $(\mathcal{H}_t)_{t \geq 0}$ describes the accessible information for the investors. Remark that the default time τ is a $(\mathcal{H}_t)_{t \geq 0}$ stopping time for all the four levels of information we consider.

3.1 Full information

PROPOSITION 3.1. If $\mathcal{H}_t = \mathcal{G}_t^M$ is the full information, then under Assumption 2.1, we have for any $\theta > t$,

$$\mathbb{P}(\tau > \theta | \mathcal{G}_t^M) = \frac{1}{p_t(L)} [E_{\mathbb{P}}(p_\theta(x) 1_{X_\theta^* > x} | \mathcal{F}_t)]_{x=L}, \quad (3.1)$$

where $p_t(x)(\omega) = (dP_t^L/dP^L)(\omega, x)$, $P_t^L(\omega, dx)$ being a regular version of the conditional law of L given \mathcal{F}_t and P^L being the law of L .

Proof. Using the facts that \mathcal{F}_θ and $\sigma(L)$ are independent under \mathbb{Q}^L , that $E_{\mathbb{Q}^L}[(d\mathbb{P}/d\mathbb{Q}^L)|\mathcal{G}_t^M] = p_t(L)$, and that \mathbb{Q}^L is identical to \mathbb{P} on \mathcal{F}_∞ , we have

$$\begin{aligned} \mathbb{P}(\tau > \theta | \mathcal{G}_t^M) &= E_{\mathbb{P}}(1_{X_\theta^* > L} | \mathcal{F}_t \vee \sigma(L)) \\ &= \frac{1}{p_t(L)} E_{\mathbb{Q}^L}(p_\theta(L) 1_{X_\theta^* > L} | \mathcal{F}_t \vee \sigma(L)) \\ &= \frac{1}{p_t(L)} [E_{\mathbb{Q}^L}(p_\theta(x) 1_{X_\theta^* > x} | \mathcal{F}_t)]_{x=L} \\ &= \frac{1}{p_t(L)} [E_{\mathbb{P}}(p_\theta(x) 1_{X_\theta^* > x} | \mathcal{F}_t)]_{x=L}. \quad \square \end{aligned}$$

Remark. If \mathcal{F}_θ and $\sigma(L)$ are independent under \mathbb{P} , we obtain the simple formula

$$\mathbb{P}(\tau > \theta | \mathcal{G}_t^M) = P_t^{X_\theta^*}(]L, +\infty[),$$

where $P_t^{X_\theta^*}(dy)$ is the regular conditional probability of X_θ^* given \mathcal{F}_t .

3.2 Progressive information and the delayed case

The case with progressive information corresponds to the standard reduced-form modelling approach and the computation results are well known in the literature (e.g. [1,8,17]). In this case, the investor knows the information on the underlying process.

PROPOSITION 3.2. If $\mathcal{H}_t = \mathcal{G}_t = \mathcal{F}_t \vee \mathcal{D}_t$ is the progressive information, we have for $\theta > t$

$$\mathbb{P}(\tau > \theta | \mathcal{G}_t) = 1_{\tau > t} \frac{\mathbb{E}(P_\theta^L(X_\theta^*) | \mathcal{F}_t)}{P_t^L(X_t^*)}.$$

Proof. Classical computation in the progressive enlargement leads to

$$\mathbb{P}(\tau > \theta | \mathcal{G}_t) = 1_{\tau > t} \frac{\mathbb{P}(\tau > \theta | \mathcal{F}_t)}{\mathbb{P}(\tau > t | \mathcal{F}_t)} = 1_{\tau > t} \frac{\mathbb{E}(S_\theta | \mathcal{F}_t)}{S_t}, \quad \theta > t,$$

where $S_t = \mathbb{P}(\tau > t | \mathcal{F}_t)$. In our model, S is given explicitly by $S_t = \mathbb{P}(X_t^* > L | \mathcal{F}_t) = P_t^L(X_t^*)$ with P_t^L being the conditional law of L given \mathcal{F}_t . This gives the result. \square

In the classical reduced-form models, such as the Cox process model, the interpretation of the underlying process is different from the one in the model (1.1). Let $\Lambda_t = X_0 - X_t^*$. The interpretation of this positive and increasing process is the compensator of default in the reduced-form models. The default is defined as the first time that the compensator process reaches the independent upper barrier $\tilde{L} = X_0 - L$. The process Λ can be calibrated from market data and the barrier \tilde{L} is supposed to follow the unit exponential law. In this case, we recover the well-known formula $\mathbb{P}(\tau > \theta | \mathcal{F}_t) = \mathbb{E}[e^{-(\Lambda_\theta - \Lambda_t)} | \mathcal{F}_t]$ for $\theta > t$. Furthermore, if Λ is absolutely continuous w.r.t. the Lebesgue

measure, i.e. $\Lambda_t = \int_0^t \lambda_s ds$, then the positive process λ is called the default intensity. We have that the process $(1_{\tau \leq t} - \int_0^{t \wedge \tau} \lambda_s ds, t \geq 0)$ is a \mathbb{G} -martingale.

In the case with delayed information, explicit computations have been given for specific delayed information \mathbb{G}^D in the literature such as in [2,4,6,12]. Here, we just give a general computation formula without discussing the details.

COROLLARY 3.3. If $\mathcal{H}_t = \mathcal{G}_t^D = \mathcal{F}_t^D \vee \mathcal{D}_t$ is the delayed information, we have for $\theta > t$

$$\mathbb{P}(\tau > \theta | \mathcal{G}_t^D) = 1_{\tau > t} \frac{\mathbb{E}(P_\theta^L(X_\theta^*) | \mathcal{F}_t^D)}{\mathbb{E}(P_t^L(X_t^*) | \mathcal{F}_t^D)}. \quad (3.2)$$

Proof. Similar as in the progressive information case,

$$\mathbb{P}(\tau > \theta | \mathcal{G}_t^D) = 1_{\tau > t} \frac{\mathbb{P}(\tau > \theta | \mathcal{F}_t^D)}{\mathbb{P}(\tau > t | \mathcal{F}_t^D)} = 1_{\tau > t} \frac{\mathbb{E}(S_\theta | \mathcal{F}_t^D)}{\mathbb{E}(S_t | \mathcal{F}_t^D)} = 1_{\tau > t} \frac{\mathbb{E}(P_\theta^L(X_\theta^*) | \mathcal{F}_t^D)}{\mathbb{E}(P_t^L(X_t^*) | \mathcal{F}_t^D)}. \quad \square$$

3.3 Noisy full information

In this subsection, $\mathcal{H}_t = \mathcal{G}_t^I$. We consider the particular but useful case in finite horizon time T where $L_t = L + \epsilon_t$, $\epsilon_t = Z_{T-t}$, Z being a continuous process with independent increments whose marginal has density q_t (this example was introduced in Corcuera et al. [5] to study insider's portfolio optimization problems). For example, $\epsilon_t = W_{g(T-t)}$ with W an independent Brownian motion, and $g : [0, T] \rightarrow [0, +\infty)$ a strictly increasing bounded function with $g(0) = 0$.

PROPOSITION 3.4. We assume that $\mathcal{H}_t = \mathcal{G}_t^I$ is the noisy full information with $L_t = L + \epsilon_t$, $\epsilon_t = Z_{T-t}$, Z being a continuous process with independent increments whose marginal has density q_t . Then, we have for $\theta > t$,

$$\mathbb{P}(\tau > \theta | \mathcal{G}_t^I) = 1_{\tau > t} \frac{\int_{\mathbb{R}} \frac{1}{p_t(l)} E_{\mathbb{P}}(p_\theta(l) 1_{X_\theta^* > l} | \mathcal{F}_t) q_{T-t}(L_t - l) P_t^L(dl)}{\int_{\mathbb{R}} 1_{X_t^* > l} q_{T-t}(L_t - l) P_t^L(dl)}, \quad (3.3)$$

where P_t^L is a regular version of the conditional law of L given \mathcal{F}_t and $(1/p_t(l)) E_{\mathbb{P}}(p_\theta(l) 1_{X_\theta^* > l} | \mathcal{F}_t)$ is the conditional default probability for the full information on the event $\{L = l\}$ (see Proposition 3.1).

Proof. We recall that $\mathcal{G}_t^I = \mathcal{F}_t^I \vee \mathcal{D}_t$. A first step is to compute $\mathbb{P}(\tau > \theta | \mathcal{F}_t^I)$.

Let $A_\theta \in \mathcal{F}_\theta$ and h be a bounded measurable function. Using the independence of $\mathcal{F}_{\theta \vee t} \vee \sigma(L)$ and Z , we have

$$\begin{aligned} \mathbb{E}(h(L) 1_{A_\theta} | \mathcal{F}_t^I) &= \mathbb{E}(h(L) 1_{A_\theta} | \mathcal{F}_t \vee \sigma(L_t) \vee \sigma((\epsilon_t - \epsilon_s), s \leq t)) \\ &= \mathbb{E}(h(L) 1_{A_\theta} | \mathcal{F}_t \vee \sigma(L + \epsilon_t)). \end{aligned}$$

Let $P_t^L(dl)$ be the regular conditional probability of L given \mathcal{F}_t . Then for $C \in \mathcal{B}(\mathbb{R}^2)$,

$$\mathbb{P}((L, L + \epsilon_t) \in C | \mathcal{F}_t) = \int_{\mathbb{R}^2} 1_C(l, x) q_{T-t}(x - l) P_t^L(dl) dx.$$

Therefore,

$$\mathbb{E}(h(L)|\mathcal{F}_t^I) = \frac{\int_{\mathbb{R}} h(l)q_{T-t}(L_t - l)P_t^L(dl)}{\int_{\mathbb{R}} q_{T-t}(L_t - l)P_t^L(dl)}. \quad (3.4)$$

Hence, if $\theta \leq t$ we have

$$\mathbb{P}(\tau > \theta|\mathcal{F}_t^I) = \frac{\int_{\mathbb{R}} 1_{X_\theta^* > l}q_{T-t}(L_t - l)P_t^L(dl)}{\int_{\mathbb{R}} q_{T-t}(L_t - l)P_t^L(dl)}.$$

If $\theta > t$, we use the following successive conditional expectations

$$\mathbb{P}(\tau > \theta|\mathcal{F}_t \vee \sigma(L + \epsilon_t)) = \mathbb{P}(\mathbb{P}(\tau > \theta|\mathcal{F}_t \vee \sigma(L + \epsilon_t) \vee \sigma(L))|\mathcal{F}_t \vee \sigma(L + \epsilon_t)).$$

Using the fact that ϵ is independent to $\mathcal{F}_T \vee \sigma(L)$, we have

$$\begin{aligned} \mathbb{P}(\tau > \theta|\mathcal{F}_t \vee \sigma(L + \epsilon_t) \vee \sigma(L)) &= \mathbb{P}(X_\theta^* > L|\mathcal{F}_t \vee \sigma(\epsilon_t) \vee \sigma(L)) \\ &= \mathbb{P}(X_\theta^* > L|\mathcal{F}_t \vee \sigma(L)) =: h_t(L), \end{aligned}$$

where $h_t(L) = (1/p_t(L))[E_{\mathbb{P}}(p_\theta(x)1_{X_\theta^* > x}|\mathcal{F}_t)]_{x=L}$ corresponds to the conditional default probability for the full information. Therefore,

$$\mathbb{P}(\tau > \theta|\mathcal{F}_t^I) = \frac{\int_{\mathbb{R}} \frac{1}{p_t(l)} E_{\mathbb{P}}(p_\theta(l)1_{X_\theta^* > l}|\mathcal{F}_t)q_{T-t}(L_t - l)P_t^L(dl)}{\int_{\mathbb{R}} q_{T-t}(L_t - l)P_t^L(dl)}. \quad (3.5)$$

The second step to compute $\mathbb{P}(\tau > \theta|\mathcal{G}_t^I)$ is straightforward using (3.5) and the well-known relation in the progressive enlargement of filtration

$$\mathbb{P}(\tau > \theta|\mathcal{G}_t^I) = 1_{\tau > t} \frac{\mathbb{P}(\tau > \theta|\mathcal{F}_t^I)}{\mathbb{P}(\tau > t|\mathcal{F}_t^I)}. \quad \square$$

Remark. This proof can be extended to other examples in the infinite horizon. For example, let $\epsilon_t = W_{g(1/(t+1))}$ with W an independent Brownian motion, and $g : [0, 1] \rightarrow [0, +\infty)$ a strictly increasing bounded function with $g(0) = 0$. Then ϵ_t is a centred Gaussian process with independent increments. Let q_t be the density of ϵ_t . We have for $\theta > t$,

$$\mathbb{P}(\tau > \theta|\mathcal{G}_t^I) = 1_{\tau > t} \frac{\int_{\mathbb{R}} \frac{1}{p_t(l)} E_{\mathbb{P}}(p_\theta(l)1_{X_\theta^* > l}|\mathcal{F}_t)q_t(L_t - l)P_t^L(dl)}{\int_{\mathbb{R}} 1_{X_t^* > l}q_t(L_t - l)P_t^L(dl)}.$$

3.4 Credit spread

An important quantity in the credit risk analysis is the credit spread defined as the instantaneous conditional default probability at time t :

$$\lambda_t = \lim_{\Delta t \rightarrow 0} \frac{1}{\Delta t} \mathbb{P}(t < \tau \leq t + \Delta t|\mathcal{H}_t) \quad \text{a.s.}$$

In the reduced-form approach with the progressive information, it coincides with the default intensity $\lambda^{\mathbb{F}}$, which is the positive \mathbb{F} -adapted process such that $(1_{\{\tau \leq t\}} -$

$\int_0^{t \wedge \tau} \lambda_s^{\mathbb{F}} ds, t \geq 0$) is a \mathbb{G} -martingale. In the classical structural approach, the credit spread tends to zero and the intensity does not exist since the default time τ is a predictable \mathbb{F} -stopping time. The credit spread for the delayed information, i.e. when $\mathcal{H}_t = \mathcal{F}_t^D$, has been studied in many papers such as [4,6,12,16]. In this case, the credit spread is strictly positive for a short-term time.

We note that in the full information case where $\mathcal{H}_t = \mathcal{G}_t^M$, we encounter the same situation as in the classical structural model: the credit spread equals to zero since L is \mathcal{G}_t^M -measurable. For the insider with the noisy full information \mathcal{G}_t^I , Proposition 3.4 implies that the credit spread remains to be zero. Because of the additional information he has on the default barrier, there is no short-term uncertainty on the default for the insider.

4. Application and numerical illustrations

We are now ready to give explicit models for the conditional default probabilities in the different settings of information. The direct application will be the pricing of the credit derivatives such as the defaultable bonds. We implement the formulas in order to quantify numerically how the different levels of information impact the estimations of the default probabilities.

In the literature, the default threshold, if random, is generally supposed to be independent of the filtration \mathbb{F} generated by the firm value process. In this case, the (H)-hypothesis is satisfied and the computations can be often simplified. In the following, we first consider an independent threshold case. Moreover, we also give an example where the default threshold is correlated to the underlying process X .

We consider the standard Black–Scholes model for the asset values process X :

$$\frac{dX_t}{X_t} = \mu dt + \sigma dB_t, \quad t \geq 0,$$

where μ and σ are real constants and B is an \mathbb{F} -Brownian motion. For $t \geq 0$ and $h, l > 0$, one has ([1, p. 69])

$$\begin{aligned} \mathbb{E}_{\mathbb{P}}(1_{X_t^* > l} - 1_{X_{t+h}^* > l} | \mathcal{F}_t) &= 1_{X_t^* > l} \left(\Phi \left(\frac{-Y_t^l - \nu h}{\sigma \sqrt{h}} \right) + e^{2\nu\sigma^{-2}Y_t^l} \Phi \left(\frac{-Y_t^l + \nu h}{\sigma \sqrt{h}} \right) \right) \\ &=: 1_{X_t^* > l} \Phi_{t,h}(l), \end{aligned} \quad (4.1)$$

where Φ is the standard Gaussian cumulative distribution function and

$$Y_t^l = \nu t + \sigma B_t + \ln \frac{X_0}{l}, \quad \text{with} \quad \nu = \mu - \frac{1}{2} \sigma^2.$$

4.1 Case of an independent default threshold

The following corollary gives the conditional default probabilities in the Black–Scholes model for any independent default threshold.

COROLLARY 4.1. We assume that the default threshold L is independent of \mathcal{F}_T . If the asset process X satisfies the Black–Scholes model, then for any $h > 0$, we have

- $\mathbb{P}(t+h \geq \tau > t | \mathcal{G}_t^M) = 1_{\tau > t} \Phi_{t,h}(L).$

- $\mathbb{P}(t+h \geq \tau > t | \mathcal{G}_t^I) = 1_{\tau > t} \frac{\int 1_{X_t^* > l} \Phi_{t,h}(l) q_{T-t}(L_t - l) P_t^L(\mathrm{d}l)}{\int 1_{X_t^* > l} q_{T-t}(L_t - l) P_t^L(\mathrm{d}l)}.$
- $\mathbb{P}(t+h \geq \tau > t | \mathcal{G}_t) = 1_{\tau > t} \frac{\int \Phi_{t,h}(l) P^L(\mathrm{d}l)}{\int 1_{X_t^* > l} P^L(\mathrm{d}l)}.$
- $\mathbb{P}(t+h \geq \tau > t | \mathcal{G}_t^D) = 1_{\tau > t} \frac{\int (\Phi_{t-\delta(t),h+\delta(t)}(l) - \Phi_{t-\delta(t),\delta(t)}(l)) P^L(\mathrm{d}l)}{\int (1 - \Phi_{t-\delta(t),\delta(t)}(l)) P^L(\mathrm{d}l)},$

where $\Phi_{t,h}$ is defined in (4.1) and $\delta(t)$ is the time delay.

We give numerical comparisons of the conditional default probabilities for different information in the following binomial example, where $l_i \leq l_s$ are the two numerical levels of the threshold. Let $0 < \alpha < 1$ and

$$L = \begin{cases} l_i & \text{with probability } \alpha, \\ l_s & \text{with probability } 1 - \alpha. \end{cases} \quad (4.2)$$

In the simulation, we take the values: $l_i = 1, l_s = 3, \alpha = (1/2)$.

Comments: The probabilities of default for a full or noisy full information are significantly different from the ones for the progressive or the delayed information. More precisely, if $L = l_i$, the manager has fixed the lower value for the default threshold and thus the probability of default will be lower for the full information than for the progressive information (see Figure 1), conversely if $L = l_s$, see Figure 2.

In both cases, the estimation of the default probability for the noisy full information is between the estimations of the full and the progressive information. The difference between the probabilities of default is very significant at the beginning and tends to vanish as time t goes to maturity T . If L is constant ($l_i = l_s$), the probabilities of default are the same, whatever the information we consider (see Figure 3). Not surprisingly, we observe that the variation of the default probabilities is closely related to the variation of the firm value. We note finally that the results between the progressive and the delayed information are very close because we have chosen a small constant delay time.

4.2 Case of a dependent default threshold

In practice, the value of the firm or its forecasting plays an important role in the manager's decision to fix the default threshold. In the following, we consider the example where

$$L = l_i 1_{[a, +\infty[}(X_A) + l_s 1_{[0, a[}(X_A), \quad A > T, \quad l_i \leq l_s. \quad (4.3)$$

The manager chooses the level of L according to a constant threshold a and to the value of the asset process X on some given date A ($A > T$ where T is a fixed horizon time, for example the maturity of the credit derivatives we consider).² If $X_A \geq a$, the manager believes that the firm is in healthy situation and chooses the lower barrier l_i , otherwise, he chooses the higher barrier to accelerate the default.

We begin by computing the default probability for the managers. By Proposition 3.1, $\mathbb{P}(\tau > t + h | \mathcal{G}_t^M) = (1/p_t(L)) [E_{\mathbb{P}}(p_{t+h}(l) 1_{X_{t+h}^* > l} | \mathcal{F}_t)]_{l=L}$. Compared with the previous

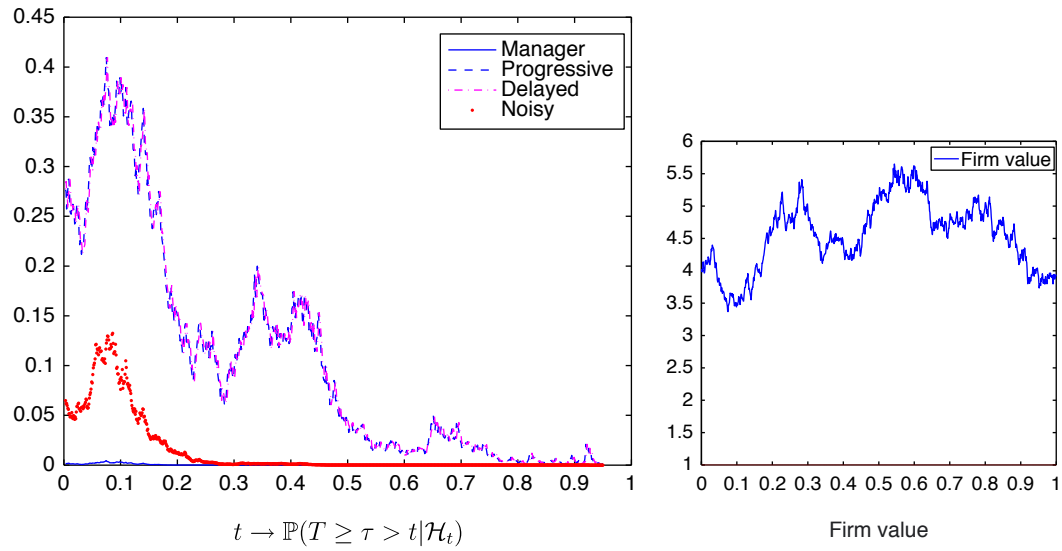

Figure 1. $L = l_i$.

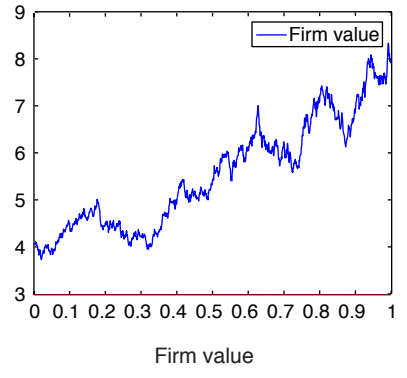

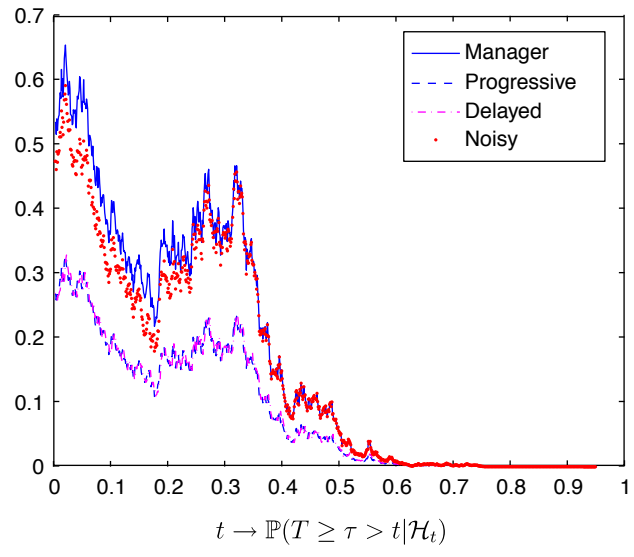

Figure 2. $L = I_s$.

independent case, we first compute the conditional law of L given \mathcal{F}_t and then the conditional joint law $(p_{t+h}(l), 1_{X_{t+h}^* > l})$ given \mathcal{F}_t .

- We have explicitly for $t < A$

$$\mathbb{P}(L = l_s | \mathcal{F}_t) = \mathbb{P}(X_A < a | \mathcal{F}_t) = \Phi(k_t), \quad \mathbb{P}(L = l_i | \mathcal{F}_t) = 1 - \Phi(k_t),$$

where

$$k_t = \frac{\ln a - \ln X_0 - \nu A - \sigma B_t}{\sigma \sqrt{A - t}}.$$

Hence,

$$p_t(l_s) = \frac{\Phi(k_t)}{\Phi(k_0)}, \quad p_t(l_i) = \frac{1 - \Phi(k_t)}{1 - \Phi(k_0)}.$$

- Using the following lemma given in [1], we deduce the conditional joint law of $(Y_{t+h}^l, 1_{X_{t+h}^* > l})$ and $(p_{t+h}(l), 1_{X_{t+h}^* > l})$ given \mathcal{F}_t .

LEMMA 4.2. For $y \geq 0$, on the set $\{\tau > t\}$

$$\mathbb{P}\left(Y_{t+h}^l \geq y, 1_{X_{t+h}^* > l} | \mathcal{F}_t\right) = \Phi\left(\frac{-y + Y_t^l + \nu h}{\sigma \sqrt{h}}\right) - e^{2\nu\sigma^{-2}y} \Phi\left(\frac{-y - Y_t^l + \nu h}{\sigma \sqrt{h}}\right),$$

where Φ is the standard Gaussian cumulative distribution function, $Y_t^l = \nu t + \sigma B_t + \ln(X_0/l)$ and $\nu = \mu - (1/2)\sigma^2$.

We denote by $f_{t,\theta,l_s}(y)$ the conditional density defined by $f_{t,\theta,l_s}(y) = (\partial/\partial y)\mathbb{P}(Y_\theta^l \geq y, 1_{X_\theta^* > l_s} | \mathcal{F}_t)$.

- Combining these two results, we have for $\theta > t$,

$$\mathbb{P}(\tau > \theta | \mathcal{G}_t^M) = 1_{L=l_s} \frac{1}{\Phi(k_t)} \mathbb{E}(\Phi(k_\theta) 1_{X_\theta^* > l_s} | \mathcal{F}_t) + 1_{L=l_i} \frac{1}{1 - \Phi(k_t)} \mathbb{E}((1 - \Phi(k_\theta)) 1_{X_\theta^* > l_i} | \mathcal{F}_t),$$

where $\Phi(k_t) = g_{l_s}(Y_t^{l_s})$ with $g_{l_s}(x) = \Phi(\ln(a/l_s) - x - \nu(A - t)/\sigma \sqrt{A - t})$ and

$$\mathbb{E}(\Phi(k_\theta) 1_{X_\theta^* > l_s} | \mathcal{F}_t) = \mathbb{E}(g_{l_s}(Y_\theta^{l_s}) 1_{(Y_\theta^{l_s})_\theta^* > 0} | \mathcal{F}_t) = 1_{X_t^* > l_s} \int_0^\infty g_{l_s}(y) f_{t,\theta,l_s}(y) dy,$$

$$\mathbb{E}((1 - \Phi(k_\theta)) 1_{X_\theta^* > l_i} | \mathcal{F}_t) = 1_{X_t^* > l_i} \int_0^\infty (1 - g_{l_i}(y)) f_{t,\theta,l_i}(y) dy.$$

This gives the conditional default probability for the full information.

The result for the noisy information is then straightforward using of Proposition 3.4. The progressive and the delayed case are obtained by classical computations. For the numerical illustrations, we have similar observations to those of the previous section.

5. Conclusions

We have investigated the impact of different information levels on the conditional default probabilities. The conditional survival probability plays an important role in the pricing of

credit derivatives (we refer the reader to a forthcoming work [13]). For example, let us consider a defaultable bond with zero recovery, that is, the buyer of the bond receives 1 euro if there is no default and zero otherwise. Then the price of such a product is exactly the conditional survival probability with respect to the accessible information.

Although the information on the value process of the firm has been widely studied, relatively few works concern the information on the default threshold. Our approach combines the initial and the progressive enlargement of filtrations in the modelling of information flows. Our results show that the information on the default threshold also has a significant influence in the credit risk analysis and deserves to be studied in more detail.

Notes

1. In the classical reduced-form model such as the Cox-process model in Lando [18], X is an increasing process – the compensator process of default – instead of a decreasing one, and L is an upper bound. See §3.2 for details.
2. In this example, the manager knows well the economic situation of the firm so that he has a good prior judgement on whether or not the terminal value of the firm X_A will be greater or smaller than the constant threshold a .
